Effects of Distamycin A (DA) and netropsin (NP) treatment on mitotic chromosome condensation in early embryonic and late larval brain cells of *D. nasuta* were investigated. These A-T specific DNA ligands cause inhibition of condensation of the heterochromatin segments much more frequently in embryonic cells than in larval brain cells.

Materials and Methods

A wild type strain of *Drosophila nasuta* from Varanasi has been used for these studies. Eggs were collected, and larvae were reared on standard agar-cornmeal-brown sugar yeast food at 24 ± 1°C.

The following experiments were done:

(1) DA or NP treatment to embryonic or late third larval brain cells—4–5 hr old eggs of *D. nasuta* were dechorionated and exposed to 20 μg/ml DA or 20 μg/ml NP for 2 hr as described earlier. Parallel control cultures were maintained without any drug. Colchicine (1 μg/ml) was added to the same medium after 2 hr and 1 hr later, the medium was replaced by a 0.67%, trisodium citrate (hypotonic) solution. After 25 min, the cells were fixed and stained preparations were made as described earlier.

Brain ganglia excised from late third instar larvae were cultured in vitro with DA (30 μg/ml) or NP (20 μg/ml) for 16 hr. Parallel control cultures were also maintained. Colchicine (1 μg/ml) was added in the culture for the last 4 hr. After routine hypotonic treatment air dry preparations were made. All slides were stained with Giemsa, mounted in 10% aqua. and examined for condensation patterns of metaphase chromosomes.

(2) H-thymidine labeling and DA treatment to late third instar brain cells—Freshly excised brain ganglia were prefixed with 1.4% thymidine for 30 min (Act. 20 μC/ml, Sp. Act. 15.2 Ci/mM, BARC, Trombay), washed and transferred to fresh radio-isotope free medium containing 20 μg/ml DA and 0.2 μg/ml colchicine for 16 hr. Air dry preparations were made after prefixed hypotonic treatment. They were rinsed in absolute alcohol, coated with Ilford L 4

Results
As described earlier, the chromosomes of *D. melanogaster* 2N = 8 in control preparations are characterized by the presence of large blocks of densely stained acrocentric heterochromatin on all chromosomes except the 1st like 4th chromosome pair. A large number of diploid and many tetra- and octaploid metaphases are present in preparations of treated larval brain ganglia made after 4 hr or 16 hr long colchicine treatments. Fresh materials and methods. Each of the metaphase plate present in preparations of DA or NP treated embryonic and larval brain cells has been examined with respect to condensation patterns of heterochromatin blocks on different chromosomes and on this basis classified into (a) normal, with the heterochromatin segments of all chromosomes in the plate remaining normally condensed, and (b) affected, in which the condensation of heterochromatin segments of some or all chromosomes has been inhibited to varying degrees. The condensation pattern of euchromatin regions in the treated metaphases has not been taken into consideration since in many non-treated control metaphases from embryos as well as larval brain, the euchromatin regions are seen to be condensed to varying degrees, ranging from very diffused to typically condensed types. Thus classification of euchromatin regions of treated metaphases into normal and affected types can be subjective and has been avoided. Data on the frequencies of normal and affected metaphases in DA or NP treated early embryos and larval brain ganglia are presented in Table 1. A large number of more than a thousand metaphases in control preparations have been examined in this and other studies and none of them are classifiable as affected types. Therefore data on control are not included in the table. Data on the 2N metaphases in DA treated brain ganglia are from only the 4 hr colchicine exposed samples while for the 4N metaphases, data from 4 hr and 16 hr (4N-thymidine experiment) colchicine exposed DA treated ganglia are pooled. All the 6N metaphases in DA treated brain ganglia have been seen in preparations of 4 hr colchicine treated series. Hyperdiploid (4N or 8N) metaphases have not been found in the NP treated ganglia samples except for three unusual 4N metaphases mentioned later. It is seen from the data in Table 1 that DA affects heterochromatin condensation in a greater proportion of embryonic metaphase cells than NP although in larval brain their effect is similar. However it is more interesting to note that for both the DNA ligands, the mitotic cell population in early embryos is much more sensitive than the mitotic cells in larval brains since the frequencies of affected metaphases are significantly higher (P<0.01 on contingency *x*² test) in embryonic than in larval brain samples treated with the same drug.

Some examples of the affected metaphases in DA or NP treated cells are presented in Fig.1. Qualitatively, inhibition of heterochromatin condensation in the affected metaphases from DA or NP treated embryonic and brain cell preparations are comparable. The degree of condensation inhibition varies between different affected cells, but in a given affected cell, the heterochromatin segments of all chromosomes are decondensed to similar degree. Condensation of the balanced heterochromatin is not affected by DA or NP treatments since even in the affected 4N or 8N metaphases, all the Y chromosomes appear normally condensed (Fig. 1 b-d). In the affected 4N or 8N metaphases, in which the euchromatin regions are diffuse, a small segment at the junction of euchromatin and heterochromatin on one of the arms of the metacentric 2nd chromosome remains normally condensed and appears more darkly stained in arrow in Fig. 1 a). In some rare 4N metaphases the hetero- as well as

Euchromatin regions in different chromatids appear differentially affected, since, while some chromatids are normally condensed, others are less condensed (Fig. 1d).

In some of the embryonic preparations, parts of euchromatin regions of different chromosomes appear as highly condensed irregular masses which may fuse with each other into one or more darkly stained bodies as observed earlier after H treatment (see Fig. 1d and e of ref. 5). A comparable effect has not been seen in larval brain preparations.

Three tetraploid metaphases in NP-treated brain ganglia display an unusual configuration (Fig. 1e). In these, the euchromatin regions of all chromosomes

show two pairs of more or less normally condensed chromosomes. Curiously, in most instances, the tips of pairs of such chromatids appear continuous (arrows in Fig. 1c). The sister heterochromatin regions of a chromosome are closely synapsed and perhaps also have a comparable tetradsomatin structure.

H-thymidine labelling patterns in DA treated affected and normal larval brain metaphases. The brain ganglia have been pulse labelled for 30 min just before the 1 hr DA and colchicine treatment. Colchicine has been kept in the medium along with DA so that all the cells that enter mitotic division during the treatment period get blocked at metaphase, and on this basis of their autoradiographic labelling patterns, they could be assigned to DNA synthetic or gap (G2 or G1) periods prior to the treatment. All the diploid and tetraploid metaphases have been scored for the patterns of autoradiographic labelling and for condensation of heterochromatin. The labelled metaphases have been classified into both or single chromatid labelled types and each of the classes further sub-divided into (i) only euchromatin, (ii) only heterochromatin and (iii) mixed heterochromatin labelled types (Table 2). Some examples are shown in Fig. 2.

All metaphases with inhibition of heterochromatin condensation Not. = normally-condensed metaphases

Discussion

The present observations on the effects of prefusion treatment of live cells of D. melanogaster with DA and NP on the condensation of A-T rich heterochromatin in mitotic chromosomes are in general agreement with our previous results with H7. Like H, both DA and NP inhibit pericentric condensation of heterochromatin. However, there are some differences in the condensation inhibition assays of the three DNA ligands on D. melanogaster chromosomes. With DA and NP we have observed that the conformation of Y chromosome heterochromatin is not inhibited in the affected metaphases while with H the Y chromosome condensation was found to be as much inhibited as that of the other chromosomal heterochromatin. This difference in the effects of these three DNA ligands is perhaps related to a heterogeneity in the constitution of heterochromatin of Y and other chromosomes of D. melanogaster and to the differences in the modes of binding of these ligands to A-T rich DNA sequences.

With respect to the frequencies of affected metaphases in the treated embryos, cells while H was found to cause condensation inhibition in 100% metaphases, DA and NP cause inhibition in only about 80% and 50% of metaphases, respectively (see Table 1). The above mentioned differences in the binding properties of these three DNA ligands are perhaps also responsible for the differences in the frequencies of the affected metaphases. In spite of these differences in their effects, all the three DNA ligands share an important feature, i.e. the frequency of affected metaphases is significantly higher in the treated early embryonic cells than in larval brain ganglia. In relation to our earlier observations with H7, we had considered it unlikely that the less frequent affect in larval brain metaphases is due to factors like low permeability of H in larval brain cells or a higher threshold level of the drug requirement to cause condensation inhibition. We believe that the same arguments also apply to our present results with DA and NP.

Mitotic chromosome condensation in cells exposed to the A-T specific DNA ligands very late in G2 period is not affected. In another study (MS in preparation), we have found that the G2 period in mitotically active larval brain cells is considerably variable and thus the failure of the A-T ligands to cause condensation inhibition in a large proportion of brain metaphases could possibly be attributed to cells which were blocked in G2 beyond the sensitive period and which enter mitosis after variable time intervals. However, the present observations on tetraploid and 3H-thymidine labelled metaphases show that this is not so since cells which transition through the entire G2 period for one or even more cycles in the presence of the A-T ligands have been found to remain unaffected as frequency of

---

Table 1: The above mentioned differences in the binding properties of these three DNA ligands are perhaps also responsible for the differences in the frequencies of the affected metaphases.
those which might have been blocked in G2 period beyond the so-called sensitive stage. The colchicine induced tetraploid metaphases would have traversed through at least one complete cell cycle in the presence of DA and yet, the frequency of affected 4N cells is as low as that in diploid metaphases. Observations on brain ganglia prelabelled with 3H-thymidine and chased in DA + colchicine medium also show that cells which were at different phases of the S-period immediately prior to DA treatment remain as frequently unafflicted as the unlabelled metaphases (G2 or G1 cells).

Inhibition of condensation in all the both chromosomes euchromatin labelled metaphases (see Fig.2a and Table 2) may lead one to suspect that early S may be the sensitive stage. However, all the euchromatin labelled 4N metaphases and about 67% of the single chromatid euchromatin labelled diploid metaphases (Fig.2b) in the same population show normal condensation. Both these categories of cells would be in second cycle after the early S label incorporation. Thus our data do not provide any evidence for early S being the sensitive stage for the condensation inhibitory action of these DNA ligands. Our data further show that cells with a shorter cell cycle (single chromatid labelled 2N and 4N metaphase) and those with a longer cell cycle period (both chromatids labelled 2N metaphases) do not differ in their sensitivity to DA.

The three metaphases classified as 4N(2N) showed in the NP treated brain ganglia preparations are interesting. In view of the reported induction of endoreplication by the H treatment in mammalian cells, 4,5,6 it is possible that these three mitotic cells also endoreduplicated after their tetraploidization due to colchicine, so that each chromosome appears as diplochromosome. However, the distinct continuity of the tips of the "subchromatids" and the close synapsis of sister and grand sister heterochromatin regions of these "diplochromosomes" are most unusual and perhaps reflect certain unknown features of chromosome organization in larval brain ganglia. The presence of 3H-thymidine labelling on both chromatids of all chromosomes in at least two of the tetraploid metaphases (Fig.2d) is also unusual since normally only one chromatid of each chromosome is expected to be labelled in these colchicine arrested second cycle metaphases. 10, We

presume that this type of labelling is related to the chromosome chromosomes in brain ganglia of Drosophila larvae being bi- or polytenic. 5,7-9

In view of the above discussion, it appears to us that the absence of the condensation inhibitory effect in a majority of the A-T Rigid treated larval brain metaphases is not due to a sensitive stage not being exposed to the drug but to a refractoriness of many of the mitotically dividing brain cells to such effects. Since the undifferentiated embryonic cells of the same species are readily affected, the refractoriness of the larval brain metaphases cells is likely to be related to some changes in architecture and chromatin packing which may be associated with somatic cell differentiation. 11-13
